Abstract

We study a two-level uncapacitated lot-sizing problem with inventory bounds that occurs in a supply chain composed of a supplier and a retailer. The first level with the demands is the retailer level and the second one is the supplier level. The aim is to minimize the cost of the supply chain so as to satisfy the demands when the quantity of item that can be held in inventory at each period is limited. The inventory bounds can be imposed at the retailer level, at the supplier level or at both levels. We propose a polynomial dynamic programming algorithm to solve this problem when the inventory bounds are set on the retailer level. When the inventory bounds are set on the supplier level, we show that the problem is NP-hard. We give a pseudo-polynomial algorithm which solves this problem when there are inventory bounds on both levels. In the case where demand lot-splitting is not allowed, i.e. each demand has to be satisfied by a single order, we prove that the uncapacitated lot-sizing problem with inventory bounds is strongly NP-hard. This implies that the two-level lot-sizing problems with inventory bounds are also strongly NP-hard when demand lot-splitting is considered.

Keywords: Dynamic lot-sizing, inventory bounds, NP-hardness, dynamic programming

1 Introduction

We consider a two-level supply chain with a supplier and a retailer. The retailer has to satisfy a demand for a single item over a finite planning horizon of discrete periods. In order to satisfy the demand, the retailer has to determine a replenishment plan over the horizon, i.e. when and how many units to order. In order to satisfy the retailer’s replenishment plan, the supplier has to determine a production plan. Ordering units induce a fixed ordering cost and a unit ordering cost for both actors. Carrying units in the inventory induce a unit holding cost for both actors as well. Moreover, the quantity that can be held in inventory at each period can be limited, since inventory bounds can be imposed at the retailer level, at the supplier level or at both levels. The cost of the supply chain is given by the sum of the supplier and the retailer total costs. The two-level Uncapacitated Lot-Sizing (2ULS) problem with inventory bounds consists in determining the order and the inventory quantities at each period for both replenishment and production plans in order to satisfy the external demand while minimizing the total cost of the supply chain.

Literature review

For many practical applications, it is unreasonable to suppose that the inventory capacity is unlimited. In particular, the products that need temperature control or special storage facilities may have a limited storage capacity. This is for example the case in the pharmaceutical industry [2]. These constraints have led to the study of lot-sizing problems with inventory bounds.

The single level Uncapacitated Lot-Sizing problem with Inventory Bounds (ULS-IB) was first introduced by Love [11]. He proves that the problem with piecewise concave ordering and holding costs and backlogging can be solved using an $O(T^3)$ dynamic programming algorithm. Atamtürk and Küçükyavuz [2] study the ULS-IB
problem under the cost structure assumed in Love’s paper [11], considering in addition a fixed holding cost. They propose an $O(T^2)$ algorithm to solve the problem. They also make a polyhedral study of the ULS-IB problem [1] by considering two cost structures: linear holding costs, linear and fixed holding costs. They provide an exact separation algorithm for each problem. Toczylowski [14] addresses this problem by solving a shortest path problem in $O(T^2)$ time. More recently, Hwang and van den Heuvel [8] propose an $O(T^2)$ dynamic programming algorithm to solve the ULS-IB problem with backlogging and a concave cost structure by exploiting the so-called Monge property. Gutiérrez et al. [6] improved the time complexity by developing an algorithm that runs in $O(T\log T)$ using the geometric technique of Wagelmans and van Hoesel [17]. However, van den Heuvel et al. [15] show that their algorithm does not provide an optimal solution for the ULS-IB problem. Liu [10] proposes an $O(T^2)$ algorithm based on the geometric approach in [17] but Önal et al. [13] prove that his algorithm does not compute an optimal solution for the ULS-IB problem. Recently, Atamtürk et al. [3] propose a polyhedral study of the capacitated fixed-charge network flow problem. The capacitated lot-sizing problem with inventory capacities can be represented by this network. They generalize the flow cover and flow pack inequalities of the fixed-charge network flow problem by proposing new valid inequalities based on the path structure of the network and provide facet conditions. They also show that these inequalities are effective by using them in a branch-and-cut algorithm.

Zangwill [19] proposes an $O(LT^4)$ dynamic programming algorithm for the multi-level uncapacitated lot-sizing problem (where $L$ is the number of levels). In particular, van Hoesel et al. observe that Zangwill’s algorithm runs in $O(T^3)$ when $L = 2$ [16]. More recently, Melo and Wolsey [12] improve this complexity by proposing an $O(T^2\log T)$ dynamic programming algorithm. Zhang et al. [20] propose a polyhedral study of the multi-level lot-sizing problem where each level has its own external demand. They give an $O(T^4)$ dynamic programming algorithm to solve the two-level problem. A few papers deal with the 2ULS problem with inventory bounds. Jaruphongsa et al. [9] study this problem with demand time window constraints and stationary inventory bounds at the supplier level. They impose some assumptions on the cost parameters (among them, the unit production cost is non-increasing). These assumptions make the problem solvable in $O(T^3)$ using a dynamic programming algorithm. They also prove that when each demand is satisfied by a single dispatch, the problem is NP-hard. Hwang and Jung [7] propose a dynamic programming algorithm that solves the 2ULS-IB problem with inventory bounds at the retailer level and concave costs in $O(T^4)$ which has the same complexity as the one provided in this paper. However, contrary to their result, we present a dynamic programming algorithm based on some structural properties specific to the inventory bounds for which we give correctness proofs.

Contributions

In this paper, we study the complexity of single-item 2ULS problems with inventory bounds. We consider that either the supplier, the retailer, or both of them, have a limited inventory capacity. A polynomial dynamic programming algorithm is provided to solve the problem with inventory bounds at the retailer level. The problem is shown to be weakly NP-hard when the inventory bounds are imposed at the supplier level. A complexity analysis for this class of problem is also proposed under the no lot-splitting assumption where each demand has to be satisfied by a unique order. In the sequel, we will denote 2ULS-IB$_R$ (resp. 2ULS-IB$_S$ ), the problem where at each period, the inventory quantity at the retailer (resp. supplier) level cannot exceed the inventory bound. Finally, the 2ULS-IB$_{SR}$ problem is the problem where both the supplier and the retailer have a limited inventory capacity. The following tables summarize the complexity results for the variants of the 2ULS-IB problems considered:

This paper is organized as follows. A mathematical formulation for the single-item 2ULS problem with inventory bounds is provided in Section 2. Sections 3, 4 and 6 follow the results described in Tables 1 and 2. In Section 5, we show that the 2ULS-IBSR problem is solvable using a pseudo-polynomial time algorithm.

## 2 Mathematical formulations

In this section, we describe the mathematical formulation of the 2ULS problem as well as the inventory bound constraints for the addressed problems.

Let $T$ be the number of periods over the planning horizon. We denote by $d_t$ the demand at each period $t$ for $t \in \{1, \ldots, T\}$. The retailer’s (resp. supplier’s) costs are defined by a fixed ordering cost $f_t^R$ (resp. $f_t^S$), a unit ordering cost $p_t^R$ (resp. $p_t^S$) and a unit holding cost $h_t^R$ (resp. $h_t^S$) for $t \in \{1, \ldots, T\}$. The retailer’s (resp. supplier’s) inventory bound at each period $t$ is denoted by $u_t^R$ (resp. $u_t^S$) for $t \in \{1, \ldots, T\}$.

We denote by $x_t^R$ (resp. $x_t^S$) the quantity ordered by the retailer (resp. supplier) at period $t$, $s_t^R$ (resp. $s_t^S$) the retailer’s (resp. supplier’s) inventory level at the end of period $t$ and $y_t^R$ (resp. $y_t^S$) the retailer’s (resp. supplier’s) setup variable, which is equal to 1 if an order occurs at period $t$ at the retailer (resp. supplier) level and 0 otherwise. The 2ULS problem can be formulated as follows:

$$\begin{align*}
\text{min} & \quad \sum_{t=1}^{T} (f_t^S y_t^S + p_t^S x_t^S + h_t^S s_t^S + f_t^R y_t^R + p_t^R x_t^R + h_t^R s_t^R) \\
\text{s.t.} & \quad s_{t-1}^R + x_t^R = d_t + s_t^R \quad \forall t \in \{1, \ldots, T\}, \\
& \quad s_{t-1}^S + x_t^S = x_t^R + s_t^S \quad \forall t \in \{1, \ldots, T\}, \\
& \quad x_t^R \leq M_t^R y_t^R \quad \forall t \in \{1, \ldots, T\}, \\
& \quad x_t^S \leq M_t^S y_t^S \quad \forall t \in \{1, \ldots, T\}, \\
& \quad x^S, x^R, s^S, s^R \geq 0 \\
& \quad y^S, y^R \in \{0,1\}^T
\end{align*}$$

where $M_t^R = M_t^S = \sum_{i=1}^{T} d_i$. The supply chain total cost is given by (1). Constraints (2) (resp. (3)) are the inventory balance constraints at the retailer (resp. supplier) level. The supplier demand is the amount ordered at the retailer level at each period $t$. Constraints (4) and (5) force the setup variables to be equal to 1 if there is an order, i.e. if $x_t^R > 0$ or $x_t^S > 0$ respectively.

The 2ULS problem can be viewed as a fixed charge network flow problem (see Figure 1) where the nodes represent the periods at each level. A source node is also considered in order to represent the total supplied quantity $\sum_{i=1}^{T} d_i$. For each node, the vertical inflows are the ordering quantities and the horizontal outflows represent the inventory quantities. In addition, arcs representing the external demand at each period at the retailer level are considered. In the sequel, we will not represent the dummy node, and the arcs will be represented only if they are active (i.e. a vertical arc will be represented if the corresponding ordering quantity is positive, and a horizontal arc is represented if the corresponding inventory quantity is not null).
In addition to this classical problem, we introduce inventory bounds constraints. The inventory bounds constraints for the 2ULS-IB\(_R\) problem are given by:

\[
    s^R_t \leq u^R_t \quad \forall t \in \{1, \ldots, T\}. \quad (8)
\]

The mathematical formulation can be strengthened by setting \(M^R_t\) to \(\min(d_t + u^R_t, \sum_{i=t}^{T} d_i)\) in the constraint (4). Similarly, the inventory bounds constraints for the 2ULS-IB\(_S\) problem are given by:

\[
    s^S_t \leq u^S_t \quad \forall t \in \{1, \ldots, T\}. \quad (9)
\]

Similarly, parameter \(M^S_t\) can be replaced by \(\min(d_t + u^S_t + u^R_t, \sum_{i=t}^{T} d_i)\) in the constraint (5). The mathematical formulation of the 2ULS-IB\(_{SR}\) problem is obtained by adding the constraints (8) and (9) to the mathematical formulation of the 2ULS problem.

3 The 2ULS-IB\(_R\) problem

The 2ULS-IB\(_R\) problem has been first studied by Hwang and Jung [7]. We present structural properties of an optimal solution for the problem and propose an \(O(T^4)\) algorithm to solve it. Since the inventory bounds are only set at the retailer level, the superscript \(R\) will be omitted in the inventory bound parameter \(u^R_t\) that will be denoted by \(u_t\).

Zangwill [19] shows that there exists an optimal solution for the 2ULS problem that verifies the Zero Inventory Ordering (ZIO) property at each level, i.e. \(s^i_{t-1} - x^i_t = 0\) for all \(t \in \{1, \ldots, T\}\) and \(i \in \{S, R\}\). As shown by [1, 14], the following assumption can be stated without loss of generality:

Assumption 1. \(u_{t-1} \leq u_t + d_t\) for all \(t \in \{1, \ldots, T\}\).

3.1 Dominance properties

In this section, we propose some dominance properties in order to determine an efficient solving approach such that there exists an optimal solution for the 2ULS-IB\(_R\) problem that satisfies these properties.

We know that the ZIO property does not hold for the ULS-IB problem [11, 10]. Let us first show that for the 2ULS-IB\(_R\) problem, the cost of the best solution in which the ZIO property is fulfilled at the retailer level may be arbitrarily large compared to the cost of an optimal solution in which the ZIO property is no required.

Property 1. For the 2ULS-IB\(_R\) problem, the cost of the best ZIO policy at the retailer level may be arbitrarily large compared to the cost of an optimal policy.

Proof. Consider the following instance \(I\): \(T = 2, h^S = p^S = f^R = h^R = [0, 0], f^S = [0, 1], p^R = [0, 1], d = [0, B + 1]\) and \(u = [B, B]\), where \(B\) is a large constant. The best solution satisfying the ZIO property at the retailer level is given by \(x^S = [d_2, 0], x^R = [0, d_2]\). The corresponding cost is \(B + 1\) whereas the optimal non-ZIO solution is given by \(x^S = [d_2, 0], x^R = [B, 1]\) inducing a cost equals to 1 (see Figure 2).
Let us now give the definition of a block (Definition 3), previously introduced in [2, 1] for the single level case.

**Definition 1 (Subplan).** Let \( i \) and \( j \) be two periods such that \( 1 \leq i \leq j \leq T \). A subplan \([i, j]\) is a partial solution at the retailer level of the 2ULS-IBR problem between the periods \( i \) and \( j \) defined by \( x_i^R, \ldots, x_j^R \).

**Definition 2 (Regular subplan).** Let \( i \) and \( j \) be two periods such that \( 1 \leq i \leq j \leq T \). A regular subplan \([i, j]\) is a subplan \([i, j]\) such that \( s_{i-1}^R \in \{0, u_{i-1}\} \) and \( s_j^R \in \{0, u_j\} \).

**Definition 3 (Block).** Let \( i \) and \( j \) be two periods such that \( 1 \leq i \leq j \leq T \). Let \( \alpha \in \{0, u_{i-1}\} \) and \( \beta \in \{0, u_j\} \). A block \([i, j]_B^R\) is a regular subplan \([i, j]\) where \( s_{i-1}^R = \alpha, s_j^R = \beta \) and \( 0 < s_t^R < u_t \) for all \( t \in \{i, \ldots, j-1\} \).

In other words, a block \([i, j]_B^R\) is a regular subplan \([i, j]\) where the inventory quantities for each period between \( i \) and \( j \) are strictly positive but not equal to the inventory bound. A regular subplan is made of one or several blocks.

**Definition 4 (Order quantity).** Let \( d_{ik} = \sum_{i=1}^{k} d_i \) be the cumulative demand between periods \( t \) and \( k \). The order quantity at the retailer level in a subplan \([i, j]\) is given by \( X_{ij} = d_{ij} - s_{i-1}^R + s_j^R \).

Observe that for a block \([i, j]_B^R\), \( X_{ij} = d_{ij} - \alpha + \beta \). Thereafter, we give some properties observed by an optimal solution for the 2ULS-IBR problem.

**Theorem 1.** Let \( \mathcal{P} \) be the set of points that satisfy Constraints (2)-(8) of the 2ULS-IBR problem. A point \((y^R, x^R, s^R, y^S, x^S, s^S) \) in \( \mathcal{P} \) is an extreme point if and only if:

1. there is at most one ordering period in every block \([i, j]_B^R\), for all \( 1 \leq i \leq j \leq T, \alpha \in \{0, u_{i-1}\}, \beta \in \{0, u_j\} \),
2. the ZIO property holds at the supplier level.

This theorem follows from the properties related to the optimal flows in a fixed-charged network with concave costs [18]. As the 2ULS-IBR problem is a single source fixed-charged network with linear costs, Theorem 1 is a direct application of the characterization of extreme points in these networks.

**Property 2.** An extreme point of \( \mathcal{P} \) satisfies the following properties at the retailer level for all \( 1 \leq i \leq j \leq T, \alpha \in \{0, u_{i-1}\}, \) and \( \beta \in \{0, u_j\} \):

(i) If \([i, j]_B^R\) is a block and if there is an ordering period in this block, then this ordering period is \( i \).

(ii) If \([i, j]_B^R\) is a block and if there is an ordering period in this block, then this ordering period is \( j \).

**Proof.** (i) If \( d_i > 0 \), then period \( i \) is necessarily an ordering period since \( s_{i-1}^R = 0 \).

If \( d_i = 0 \) and there is an ordering period in the block \([i, j]_B^R\), then we have \( s_i^R > 0 \) and period \( i \) is necessarily an ordering period since \( s_{i-1}^R = 0 \).
(ii) Assume that the (unique) ordering period is \( k \) in the block \([i,j]_{\overset{\alpha}{u}}\) with \( i \leq k \leq j-1 \). From Assumption 1, we have \( u_k \leq u_{k+1} + d_{k+1} \leq u_{k+2} + d_{k+2} + d_{k+1} \leq \cdots \leq u_j + d_j + \sum_{i=k+1}^{j-1} d_i \). Thus \( u_k \leq u_j + d_{k+1,j} \). There are two possible cases:

Case 1: \( u_k = u_j + d_{k+1,j} \). In this case, since \( s^R_k = u_j \), then \( s^R_k = u_k \) which is not possible since \([i,j]_{\overset{\alpha}{u}}\) is a block.

Case 2: \( u_{j-1} < u_j + d_j \). In this case, it is not possible to have \( s^R_i = u_j \) without having an additional ordering period in the block, which contradicts Theorem 1. So, the ordering period has to be at period \( j \) in a block \([i,j]_{\overset{\alpha}{u}}\). \( \square \)

Using Theorem 1 and Property 2, we propose a polynomial time algorithm to solve the 2ULS-IB \( R \) problem.

### 3.2 Recursion formula

In this section, we derive a polynomial backward dynamic programming algorithm to solve the 2ULS-IB \( R \) problem. The rationale of this algorithm is to compute a block decomposition of the retailer’s replenishment plan such that the total cost of the supply chain is minimized using the dominance properties of the optimal solutions of the problem.

Let \( i,j \) be two periods such that \( 1 \leq i \leq j \leq T \). Let us consider a regular subplan \([i,j]\) of a solution of the 2ULS-IB \( R \) problem. Notice that by definition \([i,j]\) is not necessarily a block unless property \( 0 < s^R_k < u_k \) for all \( k \in \{i, \ldots, j-1\} \) holds. Assume that at period \( t \), an order quantity \( X_{ij} = d_{ij} - s^R_k + s^R_k \) (see Definition 4) is available at the supplier level, \( i.e. \) it is either ordered at period \( t \) or stored at period \( t-1 \) assuming the ZIO policy. The aim is to decompose the regular subplan \([i,j]\) into blocks satisfying Property 2.

An example is given in Figure 3. The graph represents subplans of a solution for an instance of the 2ULS-IB \( R \) problem where \( T = 4 \). At period \( t = 1 \), a quantity \( X_{11} = d_1 + u_1 \) is available and at period \( t = 2 \), a quantity \( X_{24} = d_{24} - u_1 \) is available at the supplier level (it is also available at period 3). In this example, \([2,3]_{0}^{u_1} \) and \([4,4]_{0}^{0} \).

![Figure 3: Subplans decomposition for an instance of the 2ULS-IB \( R \) problem where \( T = 4 \).](image)

The recursion formula will be defined in the following order given that \([i,j]\) is an interval of periods: the cost of a block \( \phi^{\alpha \beta}_{ijk} \), the cost functions required to compute the cost of a regular subplan including the supplier’s holding cost \( w^{\alpha \gamma}_{ij} \), \( v^{\alpha \beta}_{ij} \) and \( C^{\alpha \beta}_{ij} \) and finally the cost of the supply chain \( (c^R_i) \).

#### 3.2.1 Computation of the cost of a block

Let \( \phi^{\alpha \beta}_{ijk} \) be the cost of satisfying the demands of a block \([i,j]_{\overset{\beta}{p}}\) with a single ordering at period \( k \) if it exists (Theorem 1), \( 1 \leq i \leq k \leq j \leq T \). We will denote by \( \phi^{\alpha \beta}_{ijk} \) the cost of the block \([i,j]_{\overset{\beta}{p}}\) without an ordering period.

Using Property 2(i), the cost \( \phi^{\alpha \beta}_{ijk} \) is defined as follows:

\[
\phi^{\alpha \beta}_{ijk} = \begin{cases} 
  f^R_i + p^R_i X_{ij} + \sum_{n=i}^{j} h^R_n (d_{n+1,j} + \beta), & \text{if } k = i \text{ and } 0 < d_{ij} + \beta \leq u_i \\
  0, & \text{if } i = j \text{ and } d_{ij} + \beta = 0 \\
  +\infty, & \text{otherwise.}
\end{cases}
\]
we use the notation $(X)$

## 3.2.2 Computation of the cost of a regular subplan

efficiently, we first need to find a suitable decomposition of the subplan $w$ of carrying cost for satisfying the demands of the regular subplan $\sum_{t=1}^{j} h^R(u_{t-1} - d_{in} + u_j)$, if $u_{t-1} = d_{ij} + u_j$

if $k = j$ and $d_{ij} + u_j > u_{t-1} > d_{i,j-1}$

+\infty, otherwise.

In a block $[i,j]_{0}^{u_{t-1}}$, if $u_{t-1} < d_{ij}$, then the quantity $X_{ij}$ can be ordered at any period $k$ between $i$ and $j$. In this case, we have to ensure that the inventory bounds constraints are not violated, that the inventory quantity $u_{t-1}$ covers the demands before period $k$ ($u_{t-1} > d_{i,j-1}$), and that the demands after period $k$ can be satisfied ($u_{t-1} \geq d_{k+1,j}$). The cost $\phi_{ijk}^{u_{t-1},0}$ is then given by:

$$
\phi_{ijk}^{u_{t-1},0} = \begin{cases} 
\sum_{n=1}^{j} h^R(u_{t-1} - d_{in} + u_j) + \sum_{n=k}^{j-1} h^R(u_{t-1} - d_{in}) + h^R u_j, & \text{if } d_{ij} > u_{t-1} > d_{i,j-1} \\
\sum_{n=i}^{j-1} h^R(u_{t-1} - d_{in}), & \text{if } u_{t-1} = d_{ij}
\end{cases}
$$

$$+=\infty, otherwise.
$$

### 3.2.2 Computation of the cost of a regular subplan

Let $G_{ij}^{a,b}$ be the optimal cost to cover the demands $d_{ij}$ of the regular subplan $[i,j]$ where a quantity $X_{ij}$ is available at period $t$ at the supplier level with $1 \leq i \leq j \leq T$ and $1 \leq t \leq j$, $s_{t-1} = a$ and $s_{i} = \beta$. Computing $G_{ij}^{a,b}$ requires the computation of the costs of the blocks that compose the subplan $[i,j]$. Therefore, in order to compute $G_{ij}^{a,b}$ efficiently, we first need to find a suitable decomposition of the subplan $[i,j]$.

Let $w_{ijk}^{a,b}$ be the optimal cost of the regular subplan $[i,j]$ where a quantity $X_{ij}$ is available at period $t$ at the supplier level, $k$ is a period of the first block of $[i,j]$, and if there is an order in this first block, then this order occurs at period $k$. The aim is to find the last period $l$ of the first block of the regular subplan $[i,j]$ with a possible order at period $k$ in an optimal solution. For sake of clarity, since the last period $l$ of the first block is not known, we use the notation $\gamma \in \{0,1\}$ to represent the outgoing stock at the end of the first block. Parameter $\gamma = 0$ (resp. $\gamma = 1$) means that the outgoing stock at the end of the first block is null (resp. equal to the inventory bound). The index $t,i,j,k,\alpha,\beta,\gamma$ are such that $1 \leq i \leq k < j \leq T$, $1 \leq t \leq k$, $s_{t-1} = \alpha$, $s_{i} = \beta$ and $\gamma \in \{0,1\}$. The cost $w_{ijk}^{a,b,\gamma}$ is given by:

$$
w_{ijk}^{a,b,\gamma} = \begin{cases} 
\min \{\phi_{ilk}^{a,b} + C_{il}^{a,b} + \sum_{p=1}^{k-1} h_p^X X_{ij}, & \text{if } \gamma = 0, \\
\min \{\phi_{ilk}^{a,b} + C_{il}^{a,b} + \sum_{p=1}^{k-1} h_p^X X_{ij}, & \text{if } \gamma = 1.
\end{cases}
$$

(10)

In the case where $\gamma = 1$, the first term $\phi_{ilk}^{a,b}$ in Equation (10) represents the cost of satisfying the demands of the block $[i,l]_{0}^{a}$ with a possible order at period $k$. The second term $C_{il}^{a,b}$ in Equation (10) represents the optimal cost for satisfying the demands of the regular subplan $[l+1,j]$ where $s_{l} = u_{t}$ and $s_{i} = \beta$ and assuming that the quantity $X_{l+1,j}$ is available at period $k$ at the supplier level. Finally, the last term $\sum_{p=1}^{k-1} h_p^X X_{ij}$ represents the cost of carrying $X_{ij}$ units from period $t$ to period $k$ at the supplier level. In the sequel, we define by $l_{ijk}^{a,b,\gamma}$ the period achieving the minimum of the cost $w_{ijk}^{a,b,\gamma}$, i.e. $l_{ijk}^{a,b,\gamma} = \text{argmin} w_{ijk}^{a,b,\gamma}$.

A representation of the cost $w_{ijk}^{a,b,\gamma}$ is depicted in Figure 4. There are $X_{ij}$ units available at period $t$ at the supplier level. At the retailer level, $[i,l]_{0}^{a}$ is the first block of the regular subplan $[i,j]$, where $s_{l} = u_{t}$ and $s_{i} = \beta$. A quantity $X_{ij}$ is ordered at period $k$ in this block. At the supplier level, a quantity $X_{ij}$ is stored from period $t$ to
period $k$ and an amount $X_{i,j}$ is available at period $k$ to satisfy the demands of the regular subplan $[l+1,j]$. The different terms of $w_{ij}^{\alpha\beta}$ are shown in Figure 4.

Let $v_{ij}^{\alpha\beta}$, with $1 \leq i < j \leq T$ and $1 \leq t \leq j$, be the minimum cost of a regular subplan $[i,j]$ composed of at least two blocks such that $s_{i-1}^{R} = \alpha$ and $s_{j}^{R} = \beta$ and assuming that a quantity $X_{i,j}$ is available at period $t$ at the supplier level, $1 \leq t \leq j$. The cost $v_{ij}^{\alpha\beta}$ is given by:

$$v_{ij}^{\alpha\beta} = \min_{i \leq k < j; \gamma \in \{0,1\}} \{ u_{ij}^{\alpha\gamma\beta} \}. \quad (11)$$

From the definition of the cost $v_{ij}^{\alpha\beta}$, we can then compute the cost $G_{ij}^{\alpha\beta}$ where the fixed ordering cost $f^{S}$ at the supplier level is not included. The cost $G_{ij}^{\alpha\beta}$ is given by:

$$G_{ij}^{\alpha\beta} = \begin{cases} \min \{ \min_{t \leq k \leq j} \{ \phi_{ij}^{\alpha\beta} + \sum_{l=t}^{k-1} h_{l}^{S} X_{i,j} \}, v_{ij}^{\alpha\beta} \}, & \text{if } X_{i,j} > 0, \\
\phi_{ij}^{\alpha\beta}, & \text{if } X_{i,j} = 0. \end{cases} \quad (12)$$

In Equation (12), the term $\min_{t \leq k \leq j} \{ \phi_{ij}^{\alpha\beta} + \sum_{l=t}^{k-1} h_{l}^{S} X_{i,j} \}$ represents the optimal cost of the regular subplan $[i,j]$ when it is made of a single block, and $v_{ij}^{\alpha\beta}$ is the optimal cost of $[i,j]$ when it is composed of at least two blocks. If $[i,j]^{\alpha\beta}$ is not a block or if $k < i$ then the cost $\phi_{ij}^{\alpha\beta}$ will be equal to $+\infty$. Moreover, $G_{ij}^{\alpha\beta}$ will be equal to $+\infty$ if $i > j$ or $t > j$.

### 3.2.3 Computation of the cost of the supply chain

Let $C_{ii}^{a}$ be the optimal cost of the supply chain for satisfying the demands $d_{iT}$ of the regular subplan $[i,T]$ where $s_{i}^{R} = 0$ and the first ordering period at the supplier level is larger than or equal to $t$, with $1 \leq i \leq T$, $1 \leq t \leq T$, $\alpha \in \{0,u_{i-1}\}$. The total ordering quantity of the subplan is equal to $X_{i,T}$. The aim is to determine the ordering periods satisfying the ZIO property at the supplier level in order to satisfy the demands of the regular subplan $[i,T]$.

If $X_{iT} = 0$, then no order is required at the supplier level. The cost is then equal to the cost $G_{ii}^{0}$ of the subplan $[i,T]$ with $s_{i-1}^{R} = \alpha$:

$$C_{ii}^{a} = G_{ii}^{0}. \quad (13)$$

If $X_{iT} > 0$, then the quantity $X_{iT}$ is completely or partially ordered at period $t$ or at a subsequent period if no order occurs at period $t$ at the supplier level. The cost $C_{ii}^{a}$ is given by the following equation where $1(x)$ is a
function which is equal to 0 if \( x = 0 \) and \( +\infty \) otherwise (see Figure 5).

\[
C^a_{ti} = \min \{ C_{t_i}^a, f^S_{t_i} + p^S_{t_i} X_{iT} + C_{ti}^0, \\
\min_{i \leq l < T, \gamma \in \{0, u_1\}} \{ \min(f^S_{t_i} + p^S_{t_i} X_{i\gamma}, 1(X_{i\gamma})) + C_{t_i}^a + C_{t_i}^\gamma + C_{t_i}^{a\gamma} + C_{t_i}^{a\gamma} + C_{t_i}^{a\gamma} \} \},
\]

where \( t^* \) is the last ordering period at the retailer level in the regular subplan \([i, l]\) (\( t^* \) is determined and stored when the cost \( C_{t_i}^{a\gamma} \) is computed). The period \( t^* + 1 \) is the earliest ordering period from which the supplier can order for satisfying the demands of the regular subplan \([i + 1, T]\). If there is no ordering period in the regular subplan \([i, l]\), then we set \( t^* = t \).

The first term in Equation (14) corresponds to the case where there is no order at period \( t \) at the supplier level. The second term in Equation (14) corresponds to the case where a quantity \( X_{it} \) is ordered at period \( t \) at the supplier level. Finally, the last term in Equation (14) represents the case where the quantity \( X_{it} \) is partially ordered at period \( t \) at the supplier level: a quantity \( X_{it} > 0 \) is ordered at period \( t \) to satisfy the demands of the regular subplan \([i, l]\) with \( i \leq l < T \). Because of the ZIO property at the supplier level, the supplier orders the quantity \( X_{it} \) after period \( t^* \).

A representation of the last term of the cost \( C_{ti}^a \) is provided in Figure 5. In this figure, a quantity \( X_{il} \) of units is ordered at period \( t \) at the supplier level for satisfying the demands of the regular subplan \([i, l]\) where \( s^R_{i-1} = \alpha \) and \( s^R_{l} = \gamma \in \{0, u_1\} \). The period \( t^* \) corresponds to the last ordering period in the regular subplan \([i, l]\). Since the ZIO property holds at the supplier level, we know that \( s^R_{s^R_{il}} = 0 \). Then, the next likely candidate for an ordering period at the supplier is the period \( t^* + 1 \) if it exists. The components in the definition of the cost \( C_{ti}^a \) are depicted in the figure.

Figure 5: Illustration of the cost \( C_{ti}^a \) where \([i, T]\) is a regular subplan and \( t \) is an ordering period at the supplier level.

### Optimal cost.

The optimal cost of satisfying the demands of the regular subplan \([1, T]\) is given by \( C^0_{11} \) since \( s^R_0 = 0 \) and the earliest order period at the supplier level is \( t = 1 \).

#### 3.2.4 Complexity analysis

A pre-processing phase will consist of the computation of \( d_{ij} \) for all \( j \in \{1, \ldots, T\} \) in \( O(T) \). Therefore, each \( d_{ij} \) for all \( i, j \in \{1, \ldots, T\} \) can be computed in constant time. Moreover, the holding costs required in the computation of each cost component is pre-computed and stored in \( O(T^2) \).

Therefore, the cost \( \phi^a_{ij} \) can be computed and stored in \( O(T^3) \) for all \( i, j, k \in \{1, \ldots, T\} \). Besides, it takes \( O(T^4) \) time to compute and to store the costs \( C^a_{ti} \) and \( C^a_{ti} \). Finally, the cost \( w^a_{ij} \) is computed in \( O(T^5) \), and then the time complexity of the dynamic programming algorithm based on the recursion formula (14) to compute \( C^0_{11} \) is \( O(T^5) \).

In what follows, we show how the time complexity of computing the cost \( w^a_{ij} \) can be improved from \( O(T^5) \) to \( O(T^4) \) by generalizing the result of Atamtürk and Küçükyavuz [2] for the 2ULS case. To this end, we first need
to recall the observation of Atamtürk and Kılıçkyavuz [2] for the retailer level. We provide a detailed explanation of the observation in A.

**Observation 1.** For all $1 \leq i \leq k \leq T$, $\alpha \in \{0, u_{i-1}\}$ and $\beta \in \{0, u_j\}$, we have:

(i) if $\phi_{ij}^{\alpha \beta} = +\infty$, then $\phi_{i-1,j,k}^{\alpha' \beta} = +\infty$ where $\alpha' = 0$ if $\alpha = 0$ and $\alpha' = u_{i-2}$ if $\alpha = u_{i-1}$.

(ii) if $\phi_{ij}^{\alpha \beta} \neq +\infty$, then $\phi_{i-1,j,k}^{0 \beta} = +\infty$.

(iii) if $\phi_{ij}^{u_i-1 \beta} \neq +\infty$, then:

$$\phi_{i-1,j,k}^{u_i-1 \beta} = \begin{cases} 
\phi_{ij}^{u_i-1 \beta} + \Delta_1, & \text{if } u_{i-2} > d_{i-1,k-1}, u_{i-2} < u_{i-1} + d_{i-1} \text{ and } d_{ij} + \beta > u_{i-1} \\
\phi_{ij}^{u_i-1 \beta} + \Delta_2, & \text{if } u_{i-2} > d_{i-1,k-1}, u_{i-2} < u_{i-1} + d_{i-1} \text{ and } d_{ij} + \beta = u_{i-1} \\
+\infty, & \text{otherwise}
\end{cases}$$

where $\Delta_1 = h_{i-2}^R u_{i-2} + (p_k^R - \sum_{l=i-1}^{k-1} h_l^R)(u_{i-1} - u_{i-2})$, $\Delta_2 = f_k^R + \Delta_1$.

The observation below is deduced from Observation 1 and Assumption 1. It will be used to compute efficiently the cost $w_{t,i,j,k}^{u_i-1 \gamma \beta}$.

**Observation 2.** For fixed periods $t, j, k$ such as $1 \leq k \leq j \leq T$ and $1 \leq t \leq k$, $t_{i-1,j,k}^{u_i-1 \gamma \beta} = t_{t,i,j,k}^{u_i-1 \gamma \beta}$ for all $1 \leq i \leq k$.

Proof. Let $t, i, j, k$ be periods such as $1 \leq i \leq k \leq j \leq T$ and $1 \leq t \leq k$. Let $l$ be a period between $k$ and $j$. Two cases have to be considered:

- Case 1: $d_{il} + \beta > u_{i-1}$ where $\beta \in \{0, u_i\}$.

Let us show that for each period $n \in \{l+1, \ldots, k\}$, we have $d_{in} + \beta > u_{i-1}$ where $\beta \in \{0, u_n\}$. Let $n > l$ and $\beta = u_n$ (the proof for $\beta = 0$ is similar). We have $d_{in} + u_n = d_{i,n-1} + d_n + u_n \geq d_{i,n-1} + u_{n-1} \geq \ldots \geq d_{il} + u_l > u_{i-1}$ from Assumption 1. Thus, for fixed periods $t, j, k$ and $\gamma = 0$ (the proof is similar for $\gamma = 1$), from Observation 1 and the previous remark, if $u_{i-2} > d_{i-1,k-1}$, $u_{i-2} \leq u_{i-1} + d_{i-1}$ and there exists a period $l$ between $k$ and $j$ such that $d_{il} > u_{i-1}$, we have:

$$w_{t,i,j,k}^{u_i-1 \beta} = \min_{k \leq l < j} \{ \phi_{i-1,j,k}^{u_i-1 \beta} + \sum_{p=l}^{k-1} h_p^S X_{i-1,j} \}$$

$$= \min_{k \leq l < j} \{ \phi_{i-1,j,k}^{u_i-1 \beta} + \sum_{p=l}^{k-1} h_p^S X_{i-1,j} + \Delta_1 \}$$

$$= w_{t,i,j,k}^{u_i-1 \beta} + \sum_{p=l}^{k-1} h_p^S (u_{i-1} - u_{i-1} + d_{i-1}) + \Delta_1 \leq (15)$$

Equation (15) comes from Observation 1 and the fact that $\Delta_1$ is independent of $l$. The ordering quantity $X_{i-1,j}$ of a regular subplan $[i-1, j]$ consists of the ordering quantity $X_{ij}$ of a regular subplan $[i, j]$ plus the quantity $u_{i-1} - u_{i-2} + d_{i-1}$ which leads to Equation (16).

- Case 2: $d_{il} + \beta = u_{i-1}$ where $\beta \in \{0, u_i\}$. In that case, for all periods $n < l$, we cannot have $d_{in} + \beta > u_{i-1}$ otherwise we fall into the previous case. Moreover, for all periods $n > l$, since $d_{il} + \beta = u_{i-1}$, the regular subplan $[i, n]$ where $s_{i-1}^R = u_{i-1}$ and $s_i^R \in \{0, u_n\}$ cannot be a block.

Then, similarly to the previous case, for fixed periods $t, j, k$ and $\gamma = 0$, if $u_{i-2} > d_{i-1,k-1}$, $u_{i-2} \leq u_{i-1} + d_{i-1}$ and there exists a period $l$ between $k$ and $j$ such that $d_{il} = u_{i-1}$, we have:

$$w_{t,i,j,k}^{u_i-1 \beta} = w_{t,i,j,k}^{u_i-1 \beta} + \sum_{p=l}^{k-1} h_p^S (u_{i-1} - u_{i-1} + d_{i-1}) + \Delta_2 \leq (16)$$
If $u_{i-2} > d_{i-1,k-1}$ or $u_{i-2} < u_{i-1} + d_{i-1}$ or the assumption of Case 1 or the one of Case 2 are not satisfied, then we set $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}} = +\infty$. Therefore, for fixed periods $t, j, k$ and $1 \leq i \leq k$, we have $l_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}} = l_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}}$.

The cost $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}}$ can be computed from $w_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}}$ independently of period $l$ by using Observation 1 and 2. For all $1 \leq i \leq T$ and given $k, t, j$, with $i \leq k < j \leq T$ and $1 \leq t \leq k$, for $\alpha \in \{0, u_{i-1}\}$, $\gamma \in \{0, 1\}$ and $\beta \in \{0, u_j\}$, the cost $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}}$ can be done in $O(T)$ time using the following equations:

(i) $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}} = +\infty$ for any value of $w_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}}$

(ii) $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}} = \begin{cases} w_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}} + \Delta_1 + \sum_{l=t}^{k-1} h_l^S(u_{i-1} - u_{i-2} + d_{i-1}), & \text{if } u_{i-2} > d_{i-1,k-1} \land d_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}} + \gamma \times u_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}} > u_{i-1} \\ w_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}} + \Delta_2 + \sum_{l=t}^{k-1} h_l^S(u_{i-1} - u_{i-2} + d_{i-1}), & \text{if } u_{i-2} > d_{i-1,k-1} \land d_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}} + \gamma \times u_{t_{ij-1},j,k}^{u_{i-1}d_{i-1}} = u_{i-1} \\ +\infty, & \text{otherwise.} \end{cases}$

Consequently, for fixed periods $t, k, j$, the cost $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}}$ with $1 \leq i \leq k$ can be computed in $O(T)$ time. So, for all periods $i, k, t, j$ such that $1 \leq i \leq k \leq j \leq T$ and $1 \leq t \leq k$, the cost $w_{t_{ij-1},j,k}^{u_{i-2}d_{i-1}}$ is computed in $O(T^4)$ time. This implies that the algorithm which solves the 2ULS-IB$_R$ problem runs in $O(T^4)$ time.

4 The 2ULS-IB$_S$ problem

Jaruphongsena et al. [9] propose a polynomial time algorithm to solve the 2ULS-IB$_S$ problem with demand time window constraints and stationary inventory bounds. They consider that $h^S \leq h^R$ and that the fixed ordering cost and the unit ordering cost are decreasing. These specific costs make the problem solvable in polynomial time. In this section, we consider the 2ULS-IB$_S$ problem under a general cost structure and we prove that this problem is NP-hard.

Theorem 2. The 2ULS-IB$_S$ problem is NP-hard.

Proof. We prove that the 2ULS-IB$_S$ problem is NP-hard through a reduction from the subset sum problem, which is an NP-complete problem [5]. An instance of the subset sum problem is given by an integer $S$ and a set $S$ of $n$ integers $(a_1, \ldots, a_n)$. The question is: does there exist a subset $A \subseteq S$ such that $\sum_{a_i \in A} a_i = S$?

We transform an instance of the subset sum problem into an instance of the 2ULS-IB$_S$ problem in the following way:

- $T = 2n + 1$. Let us denote by $T_1$ (resp. $T_2$) the set of odd (resp. even) periods in the set $\{1, \ldots, 2n\}$.
- $d_t = 0$ for all $t \in T_1 \cup T_2$, $d_T = S$
- $f^S_t = 1$ for all $t \in T_1$, $f^S_t = 2S$ for all $t \in T_2 \cup \{T\}$
- $f^R_t = 2S$ for all $t \in T_1 \cup \{T\}$, $f^R_t = 0$ for all $t \in T_2$
- $h^S_t = h^R_t = 0$ for all $t \in \{1, \ldots, T\}$
- $p^R_t = 0$ for all $t \in \{1, \ldots, T\}$
- $p^S_t = 1 - 1/a_{\lceil \frac{t}{2} \rceil}$ for all $t \in T_1 \cup T_2$, $p^S_T = 0$
- $u^S_t = a_{\lceil \frac{t}{2} \rceil}$ for all $t \in T_1 \cup T_2$, $u^S_T = 0$
A representation of this instance is given in Figure 6. The fixed ordering costs and the unit ordering costs of the supplier (resp. retailer) are indicated at the top (resp. bottom). At the supplier level, the quantities on the horizontal edges represent the inventory bounds.

![Figure 6: Instance $A$ of the 2ULS-IB$_S$ problem in the proof of Theorem 2 with $n = 3, S = \{a_1, a_2, a_3\}$.](image)

**Observation 3.** Note that if we order $x_i^S = a_i$ at period $t \in T_1$ then the total ordering cost is equal to $f_i^S + p_i^S x_i^S = 1 + (1 - 1/a_i) a_i$ which is exactly equal to $x_i^S$ (in this case, the average cost of ordering one unit is equal to 1). If $x_i^S < a_i$ at period $t \in T_1$, then we have that the total ordering cost $f_i^S + p_i^S x_i^S = 1 + (1 - 1/a_i) a_i x_i^S = x_i^S + 1 - x_i^S a_i > x_i^S$ (in this case, the average cost of ordering one unit is larger than 1). From this observation, let us prove that there exists a solution for the 2ULS-IB$_S$ problem of cost at most 5 if and only if there exists a solution for the subset sum problem.

Assume that there exists a solution $A$ of the subset sum problem. The following solution for the 2ULS-IB$_S$ problem is of cost at most $S$: for each element $a_i$ in the set $A$, the supplier orders a quantity $a_i$ at period $t = 2i - 1$ and store it until period $t + 1$ (see Figure 7). The inventory bound is not exceeded since it is exactly equal to $a_i$. From Observation 3 above, the cost of ordering $a_i$ units for each $a_i \in A$ at the supplier level is equal to $a_i$. Since $\sum_{a_i \in A} a_i = S$, the total cost at the supplier level is $S$. At period $t = 2i$, the retailer orders all the units and store them until period $T$. Since $f_i^R = 0$ for all $t \in T_2$ and $h_i^R = p_i^R = 0$ for all $t \in \{1, \ldots, T\}$, the total cost at the retailer level is equal to 0. So, there exists a solution for the 2ULS-IB$_S$ problem of cost $S$.

![Figure 7: Solution for the 2ULS-IB$_S$ problem in the proof of Theorem 2 with $n = 3, S = \{a_1, a_2, a_3\}$ and $a_1 + a_3 = S$.](image)

Assume that there exists a solution for the 2ULS-IB$_S$ problem with a cost of at most 5. Since $f_i^S = 25$ for all $t \in T_2$, the supplier has to order at period $t \in T_1$, otherwise the cost will exceed $S$. Likewise, since $f_i^R = 25$ for all $t \in T_1$, the retailer has to order at period $t \in T_2$. In order to not exceed the inventory bounds, the supplier can store at most $a_i^S = a_i$ units from period $t$ to period $t + 1$. Thus, the quantity ordered by the supplier at period $t \in T_1$ is at most $a_i$. At period $t \in T_2$, the retailer orders the units in the supplier’s inventory and stores them.
We have proved that the 2ULS-IBS problem is NP-hard. By setting \( u_t^R = \sum_{t=1}^T d_t \), we can transform an instance of the 2ULS-IBS problem into an instance of the 2ULS-IBSR problem. Thus, the 2ULS-IBSR problem is at least as hard as the 2ULS-IBS problem. In this section, we describe a pseudo-polynomial dynamic programming algorithm to solve the 2ULS-IBSR problem. This proves that this problem is not strongly NP-hard.

Let \( s_t^R \in \{0, 1, \ldots, u_t^R\} \) (resp. \( s_t^S \in \{0, 1, \ldots, u_t^S\} \)) be the inventory quantity available at the end of period \( t \) at the retailer (resp. supplier) level. The principle of the algorithm is to consider all the possible values of the inventory quantity \( s_t^R \) (resp. \( s_t^S \)) at the retailer (resp. supplier) level. Notice that the ZIO property does not hold neither at the supplier nor at the retailer levels for the 2ULS-IBSR problem.

Let \( C_i^j(X) \) be the cost of ordering \( X \) units at level \( i \in \{R, S\} \) at period \( t \), where the level \( R \) (resp. \( S \)) corresponds to the retailer (resp. supplier) level. The cost \( C_i^j(X) \) is given by:

\[
C_i^j(X) = \begin{cases}
 f_i^j + p_i^j X, & \text{if } X > 0 \\
 0, & \text{otherwise}.
\end{cases}
\]

We define \( V_l(s_{t-1}^R, \bar{s}, s_{t-1}^S, s) \) as the cost of satisfying the demand \( d_l \) when:

- \( s_{t-1}^R \) (resp. \( s_{t-1}^S \)) units are stored at period \( t - 1 \) and \( \bar{s} \) (resp. \( s \)) units are stored at period \( t \) at the retailer (resp. supplier) level,

- \( X^R = \bar{s} + d_l - s_{t-1}^R \) (resp. \( X^S = s + X^R - s_{t-1}^S \)) units are ordered at period \( t \) at the retailer (resp. supplier) level.

The cost \( V_l(s_{t-1}^R, \bar{s}, s_{t-1}^S, s) \) is defined by:

\[
V_l(s_{t-1}^R, \bar{s}, s_{t-1}^S, s) = \begin{cases}
 c^R(X^R) + C^S(X^S), & \text{if } \bar{s} \leq u_t^R, s \leq u_t^S \text{ and } \bar{s} + s \leq d_{lT} \\
 +\infty, & \text{otherwise}.
\end{cases}
\]

Let \( H_l(s_{t-1}^R, s_{t-1}^S) \) be the minimum cost of satisfying the demands \( d_{lT} \) where \( s_{t-1}^R \) (resp. \( s_{t-1}^S \)) units are stored at period \( t - 1 \) at the retailer (resp. supplier) level. From the definition of the cost \( V_l(s_{t-1}^R, \bar{s}, s_{t-1}^S, s) \), we can compute the cost \( H_l(s_{t-1}^R, s_{t-1}^S) \) as follows:

\[
H_l(s_{t-1}^R, s_{t-1}^S) = \min_{\bar{s} \in \mathcal{S}_R^R, s \in \mathcal{S}_S^S} \left\{ V_l(s_{t-1}^R, \bar{s}, s_{t-1}^S, s) + H_{l+1}(\bar{s}, s) \right\},
\]

where \( \mathcal{S}_R^R = \{\max(0, s_{t-1}^R - d_l), \ldots, M_t^R\} \), with \( M_t^R = \min(u_t^R, d_{lT}) \), and \( \mathcal{S}_S^S = \{\max(0, s_{t-1}^S - X^R), \ldots, M_t^S\} \), with \( M_t^S = \min(u_t^S, d_{lT}) \).

### Optimal cost

The optimal cost of satisfying the demands \( d_{1T} \) assuming that \( s_0^R = s_0^S = 0 \) is given by \( H_1(0, 0) \). We initialize the recursion by setting \( H_{T+1}(s_t^R, s_t^S) = 0 \) for all the values \( s_{t-1}^R \) and \( s_{t-1}^S \) ensuring feasibility.

The related lot-sizing problem with production capacity constraints instead of inventory bounds has been proved to be NP-hard [4]. The instance parameter \( p^S \) used in the proof of Theorem 2 is based on [4]. Moreover, it is worth noticing the inventory bound at period \( t \) acts as a production capacity since the supplier cannot supply at \( t \) the ordered units.
Complexity analysis

Computing the cost \( V_t(s_{t-1}^R, \bar{s}_{t-1}^S, s_t^R, \bar{s}_t^S) \) can be done in \( O(u_{t-1}^R u_{t-1}^S M_t^R M_t^S) \) for each period \( t \). Therefore, it takes \( O(\sum_{t=1}^T (u_{t-1}^R u_{t-1}^S M_t^R M_t^S)) \) to compute the optimal cost \( H_t(0, 0) \). This bound constitutes the complexity of the dynamic programming algorithm. This is pseudo-polynomial, implying that the 2ULS-IB\textsubscript{SR} problem is not strongly NP-hard.

In the next section, we consider the 2ULS problems with inventory bounds assuming that the demand at the retailer level has to be covered by a single order.

6 Analysis of lot-sizing problems without lot-splitting

Jaruphongsa et al. [9] introduce the problem where each demand must be satisfied by exactly one dispatch, i.e. the demand lot-splitting is not allowed at the retailer level. We called this constraint the No Lot-Splitting (NLS) constraint. In practice, this study is motivated by traceability requirements for the product where the management of the inventory and the transport can be improved if the demand is supplied from the supplier to the retailer by a single delivery. We note \( x_{kt}^R \geq 0 \) the quantity of demand \( d_t \) which is ordered at period \( k \) to satisfy a demand \( d_t \) at the retailer level. We have \( \sum_{t=1}^T x_{kt}^R = d_t \).

Definition 5 (NLS constraint). An ordering plan \( x^R \) fulfills the NLS constraint if there does not exist two periods \( l \) and \( k \) with \( l < k \leq t \) such that \( x_{lt}^R > 0 \) and \( x_{kt}^R > 0 \) for all periods \( t \).

The 2ULS-IB\textsubscript{R} and the 2ULS-IB\textsubscript{S} problems with the NLS constraint are denoted by 2ULS-IB\textsubscript{R}-NLS and 2ULS-IB\textsubscript{S}-NLS respectively. Before studying the complexity of the latter problems, it is interesting to analyze the complexity of the single level problem with NLS constraint, that we denote by ULS-IB-NLS. The proofs of the following results are given in Appendix.

We consider \( T \) periods \( \{1, \ldots, T\} \). In the ULS-IB-NLS problem, ordering units at period \( t \) induces a fixed ordering cost \( f_t \) and a unit ordering cost \( p_t \). Carrying units from period \( t \) to period \( t+1 \) induces a holding cost \( h_t \). The total cost is given by the sum of the ordering and holding costs. The aim is to determine an ordering plan which satisfies the demands and which minimizes the total cost. We denote by \( x_t \) the ordering quantity at period \( t \), \( s_t \) the inventory quantity at the end of period \( t \) and \( y_t \) the binary (setup) variable which is equal to 1 if there is an order at period \( t \) and 0 otherwise. We say that the inventory bound is stationary if \( u_t \) is constant throughout the planning horizon.

Theorem 3. The ULS-IB-NLS problem is strongly NP-hard, even if the inventory bound is stationary.

Note that ULS-IB problem can be solved in polynomial time [2, 11]. Theorem 3 shows that adding the NLS constraint to this problem makes it strongly NP-hard.

Corollary 1. The 2ULS-IB\textsubscript{R}-NLS problem is strongly NP-hard, even if the inventory bound is stationary.

Jaruphongsa et al. [9] prove that the 2ULS-IB\textsubscript{S}-NLS problem with demand time window constraints is weakly NP-hard. We show that this problem is also weakly NP-hard without demand time window constraints, and that it is even strongly NP-hard.

Corollary 2. The 2ULS-IB\textsubscript{S}-NLS is strongly NP-hard, even if the inventory bound is stationary.

Consider the case where the supplier and the retailer have inventory bounds. We prove that the 2ULS-IB\textsubscript{SR}-NLS problem is strongly NP-hard.

Corollary 3. The 2ULS-IB\textsubscript{SR}-NLS problem is strongly NP-hard, even if the inventory bound is stationary.
7 Conclusion and future work

This paper considers two-level uncapacitated lot-sizing problems with inventory bounds, and provides a complexity analysis of these problems. We present an \( O(T^4) \) dynamic programming algorithm which solves the problem where the inventory bounds are set at the retailer level. When the inventory bounds are set at the supplier level, we prove that the problem is weakly NP-hard. We also present a pseudo-polynomial dynamic programming algorithm which ensures that this problem is not strongly NP-hard. Considering that lot-splitting is not allowed, we prove that the ULS problem with inventory bounds and the 2ULS problems where the inventory bounds are set at the retailer level, or at the supplier level or at both of them are strongly NP-hard.

It would be interesting for a future work to improve the running time of the algorithm solving the 2ULS-IB problem. Moreover, the complexity of the 2ULS-IB problem where the inventory bounds of the supplier are stationary is an open problem. Another interesting perspective is to consider that the supplier and the retailer share the same inventory facility. In this case, at each period, the inventory quantity of the supplier plus the one of the retailer cannot exceed a given inventory bound. The lot-sizing problems that have been studied is this paper consider a single item. It would also be interesting to study the case where there are several items. Finally, investigating efficient algorithms to solve the NP-hard 2ULS problems with inventory bounds is also a promising issue for practical applications. In particular, it would be interesting to consider the valid inequalities proposed by [3] for solving the two-level case.

Appendix A

Proof of Observation 1. (i) If \( \phi_{ijk}^{β} = +∞ \), then the regular subplan \([i, j]\) with a single order at period \(k\), \(s_{i−1}^{R} = α\) and \(s_{j}^{R} = β\) is not a block. The violation(s) observed in the regular subplan \([i, j]\) will also hold for the regular subplan \([i−1, j]\).

(ii) If \( \phi_{ijk}^{0β} \neq +∞ \), then \([i, j]^{0}_{β}\) is a block, and by Property 2(i) there is an ordering period at \(k = i\). We consider the regular subplan \([i−1, j]\) with an order at period \(k\), \(s_{i−2}^{R} = 0\) and \(s_{j}^{R} = β\). If \(d_{i−1} = 0\), then the regular subplan \([i−1, j]\) is not a block since \(s_{i−2}^{R} = 0\). If \(d_{i−1} > 0\), then \(d_{i−1}\) could not be covered and thus the regular subplan \([i−1, j]\) is not a block.

(iii) If \( \phi_{ijk}^{u_{i−1}β} \neq +∞ \), then \([i, j]^{u_{i−1}}_{β}\) is a block with an ordering period \(k\) if it exists. We consider the regular subplan \([i−1, j]\) with a single order at period \(k\), \(s_{i−2}^{R} = u_{i−2}\) and \(s_{j}^{R} = β\). We want to determine if this regular subplan is a block.

We know that \(u_{i−2} \leq u_{i−1} + d_{i−1}\) (Assumption 1). If \(u_{i−2} = u_{i−1} + d_{i−1}\), then this regular subplan is not a block because in that case \(s_{i−1}^{R} = u_{i−1}\). If \(u_{i−2} < u_{i−1} + d_{i−1}\), the we have \(s_{i−1}^{R} < u_{i−1} \leq d_{i−1} + β\), and there must be an ordering period at \(k\) in the subplan \([i−1, j]\).

Moreover, if \(u_{i−2} > d_{i−1,k−1}\), then we have a block \([i−1, j]^{u_{i−2}}_{β}\). The retailer has to order a quantity \(u_{i−1} − u_{i−2} + d_{i−1} > 0\) in addition to \(X_{ij} = d_{ij} − u_{i−1} + β\) at period \(k\). The inventory quantities between periods \(k\) and \(j\) remain unchanged in the block \([i−1, j]^{u_{i−2}}_{β}\). Since the demand \(d_{i−1}\) has to be covered by \(u_{i−2}\), there are \(u_{i−1} − u_{i−2} + d_{i−1}\) less units in the inventory between periods \(i−1\) and \(k−1\). The cost \(\phi_{i−1,j,k}^{u_{i−2}}\) of the block \([i−1, j]^{u_{i−2}}_{β}\) can be derived from \(\phi_{ijk}^{u_{i−1}β}\) by considering these two cases:

Case 1: Assume that a quantity \(X_{ij} > 0\) is ordered at period \(k\) in the block \([i−1, j]^{u_{i−2}}_{β}\). Then, the cost of the block \([i−1, j]^{u_{i−2}}_{β}\) is given by: \(\phi_{ijk}^{u_{i−1}β} + h_{R}^{i} - u_{i−2} + (p_{R}^{i} - \sum_{a=1}^{k−1} h_{R}^{a})(u_{i−1} − u_{i−2} + d_{i−1}) = \phi_{ijk}^{u_{i−1}β} + Δ_{1}\).

Case 2: Assume that no ordering period occurs in the block \([i, j]^{u_{i−1}}_{β}\). Then, an additional fixed ordering cost \(f_{k}^{R}\) must be considered to compute the cost of the block \([i−1, j]^{u_{i−2}}_{β}\), which will be given by: \(\phi_{ijk}^{u_{i−1}β} + f_{k}^{R} + Δ_{1} = \phi_{ijk}^{u_{i−1}β} + Δ_{2}\).
Appendix B

Proof of Theorem 3. We show that the 3-Partition problem, which is strongly NP-hard [5], can be reduced to the ULS-IB-NLS problem in polynomial time. Recall that an instance of the 3-Partition problem is given by an integer \( b \) and \( 3m \) integers \((a_1, \ldots, a_{3m})\) such that \( \sum_{i=1}^{3m} a_i = mb \) and \( b/4 < a_i < b/2 \) for all \( i \in \{1, \ldots, 3m\} \). The question is: does there exist a partition \( A_1 \cup \ldots \cup A_m \) of \( \{1, \ldots, 3m\} \) such that \( \sum_{i \in A_j} a_i = b \) for all \( j \in \{1, \ldots, m\} \).

We transform an instance of the 3-Partition problem into an instance of the ULS-IB-NLS problem in the following way:

- \( T = 5m \) periods. Let us denote \( T_1 \) (resp. \( T_2 \)) the set of odd (resp. even) periods in the set \( \{1, \ldots, 2m\} \).
- \( d_t = 0 \) for all \( t \in T_1 \)
  \( d_t = (m - t/2) b \) for all \( t \in T_2 \)
  \( d_t = a_{t-2m} \) for all \( t \in \{2m+1, \ldots, T\} \)
- \( f_t = 0 \) for all \( t \in T_1 \)
  \( f_t = b + 1 \) for all \( t \in T_2 \cup \{2m+1, \ldots, T\} \)
- \( h_t = 0 \) for all \( t \in \{1, \ldots, T\} \)
- \( p_t = 0 \) for all \( t \in T \setminus \{2m - 1\} \) and \( p_{2m-1} = 1 \)
- \( u_t = mb \) for all \( t \in \{1, \ldots, T\} \)

The instance is illustrated in Figure 8. The fixed ordering costs are indicated at the top of each period. The inventory bounds are represented on the horizontal edges.

![Figure 8: Instance of the ULS-IB-NLS problem in the proof of Theorem 3.](image)

Let us show that there exists a solution to the ULS-IB-NLS problem of cost at most \( b \) if and only if there exists a solution to the 3-Partition problem.

Assume that there exists a solution \((A_1, \ldots, A_{3m})\) of the 3-Partition problem. The cost of the following solution of the ULS-IB-NLS problem is \( b \): at each period \( t \in T_1 \), we order \( x_t = \sum_{i \in A_{(t+1)/2}} a_i + d_{t+1} = b + \left( m - \frac{t+1}{2} \right) \) units. Since \( p_t = 0 \) for all \( t \in T_1 \setminus \{2m - 1\} \) and \( p_{2m-1} = 1 \), it costs \( p_{2m-1} x_{2m-1} = p_{2m-1} b = b \) to order these units. At each period \( t \in T_2 \), the demand \( d_t \) is satisfied and \( b \) units are stored which implies that there is exactly \( s_t = \frac{t}{4} b \) units in stock at the end of period \( t \). At each period \( t \in T_1 \), we store exactly a quantity \( s_{t-1} + x_t = \frac{t-1}{2} b + \left( m - \frac{t-1}{2} \right) b = mb \) and the inventory bound \( u_t \) is not exceeded. Each demand \( d_t \) for all \( t < 2m \) is satisfied and there is \( mb \) units in stock at period \( 2m \) for satisfying the demands at period \( \{2m + 1, \ldots, T\} \). Since there is no holding cost, the cost of this solution is \( b \). Note that this solution fulfills the NLS constraint since each demand is satisfied by a single order.

Assume now that there exists a solution to the ULS-IB-NLS problem of cost at most \( b \) (see Figure 9).
Proof of Corollary 1. We do a reduction from the ULS-IB-NLS problem, that is strongly NP-hard, as shown by Theorem 3. We transform an instance of the ULS-IB-NLS problem into the following instance of the 2ULS-IB-R-NLS problem. The costs of the retailer are the ones of the ULS-IB-NLS problem, i.e. \( u_t^R = u_t, f_t^R = f_t, p_t^R = p_t \) and \( h_t^R = h_t \) for all \( t \in \{1, \ldots, T\} \). The supplier costs are given by \( f_t^S = h_t^S = p_t^S = 0 \) for all \( t \in \{1, \ldots, T\} \). The demands are the same as the ones of the ULS-IB-NLS problem. Since all the supplier’s costs are zero, the cost of an optimal solution for the ULS-IB-NLS problem is equal to the optimal cost of its corresponding 2ULS-IB-R-NLS instance (see Figure 10).

By Theorem 3, the 2ULS-IB-R-NLS problem is also strongly NP-hard.

Proof of Corollary 2. As in the proof of Corollary 1, we do a reduction from the ULS-IB-NLS problem, which is strongly NP-hard, as shown in Theorem 3. We transform an instance of the ULS-IB-NLS problem into the following instance of problem 2ULS-IB

\[ \text{Figure 9: Solution for the ULS-IB-NLS problem in the proof of Theorem 3.} \]

Since all orders are set at period \( t \in T_1 \). Since for each period \( t \in T_2, d_t = (m - t/2)b \), and since the inventory bound is \( mb \), at most \( \frac{1}{2}b \) units can be stored from period \( t \in T_2 \) to a period in \( T_1 \). Since \( mb \) units have to be available at period \( 2m \) (otherwise the cost will be greater than \( b \)), then \( \frac{1}{2}b \) units have to be stored from period \( t \in T_2 \) to period \( t + 1 \). So, we have to order \( b \) units at each period \( t \in T_1 \) for satisfying the demands \( d_{2m+1} \) (we cannot order all the units at period \( 2m - 1 \) since \( p_{2m-1} = 1 \) and the cost will be greater than \( b \)). Assuming the NLS constraint, each demand \( d_t \) for all \( t \in \{2m + 1, \ldots, T\} \) is satisfied by a single ordering period at \( t \in T_1 \). So, there is a partition of the periods \( \{2m + 1, \ldots, T\} \) into \( m \) sets \( \{A_1, \ldots, A_m\} \) such that \( \sum_{i \in A_j} d_t = b \) for all \( j \in \{1, \ldots, m\} \). Since each demand \( d_t \) for all \( t \in \{2m + 1, \ldots, T\} \) corresponds to an integer of \( (a_1, \ldots, a_{3m}) \), this means that there exists a solution to the 3-Partition problem.

\[ \text{Figure 10: Solution for the 2ULS-IB-R-NLS problem in the proof of Corollary 1.} \]
Therefore, by Theorem 3, the 2ULS-IB₅-NLS problem is also strongly NP-hard.

**Proof of Corollary 3.** The proof of this corollary is the same as the one of Corollary 2 for the 2ULS-IB₅-NLS problem by adding any inventory bound at the retailer level (in an optimal solution no quantity will be stored at the retailer level).
